SHEBA

Acknowledgments

The willing cooperation of ~~the~~ <sup>and discussions with K. Minami ~~and A. Kohmura~~ manager</sup> ~~the~~ <sup>personnel</sup> ~~staff~~ of the Vancouver office of Dowa Mining Co. Ltd. <sup>R. Saleken and P. McAndless,</sup> and ~~the~~ principals of Geotec Consultants Ltd. are gratefully acknowledged.

History

Work on the property was ~~started~~ <sup>began</sup> in 1964 when Anaconda Mining Co. Ltd. <sup>built access roads and</sup> conducted geological, <sup>induced potential</sup> geochemical, and magnetometer surveys. <sup>As a result of this work</sup> ~~and~~ <sup>was drilled</sup> 11 holes with total <sup>ing</sup> footage 7585 ft were drilled. In 1965 further induced potential surveys led to 2355 feet of drilling in 6 diamond drill holes. No work was done in 1966 but Sumitomo Metal Mining Co. optioned the ground <sup>(mapping, a soil sampling program and)</sup> in 1967. <sup>more</sup> I. P. work ~~was~~ <sup>were</sup> followed up by trenching and 4000 feet of percussion drilling in <sup>15</sup> ~~16~~ holes. Much of the drilling <sup>(in geology)</sup> was on or near the Jay 19 claim. In the first 5 months of 1968 Sumitomo carried out further <sup>mapping,</sup> soil sampling and IP surveys, ~~bulldozed~~ <sup>bulldozed</sup> 42 trenches with total length 8400 feet, and did 1785 feet of percussion drilling in 5 holes. ~~late~~ in 1968 Anaconda optioned the property once again. During 1969 they <sup>geologically</sup> ~~conducted~~ mapped local areas, did <sup>line</sup> 2.3 miles of IP survey and 5214 feet of diamond drilling in ~~7~~ holes. Little was done in 1970 but in 1971 an option was taken by Dowa Mining Co. Ltd. All the claims were geologically

mapped at 1" = 400' and 279 soil samples were taken along 5.3 miles of line on claims J1 to 7, J37 fraction, J38 fraction and J104 fraction. Subsequently, 12 diamond drill holes with totalling footage 8569 feet were drilled on claims Jay 9 to 10 and 104 fraction, Cu 1, 3, 4 and 6, J4, 5, 7 and 38 and Ann 5 fraction. The 1971 drill holes <sup>and mapping done as part of the Guichon project</sup> were ~~logged~~ and are the basis of this report.   
 (by Dept. of Mines and P.R. field crews)

General Geology

The claims are underlain by granitic rocks of the Guichon Creek batholith (Figure 1) (for rock type definitions see Table <sup>shown on</sup> "A") variety (formerly called the Costcut Phase - McMillan, 1970) underlying the central part of the property and are flanked to the east and west by rocks of the Bethlehem phase. Farther east, the Bethlehem phase rocks <sup>give</sup> ~~pass~~ way to rocks of first the Guichon, then the Chataway varieties (Highland Valley phase). All the rocks are quartz diorites or granodiorites. Distinctions <sup>between them for field</sup> ~~separations~~ mapping are based on textural <sup>and color index</sup> criteria as outlined in Table 1.

The granitic rocks are cut by quartz plagioclase porphyry and aplite dikes. A small <sup>elongated</sup> body of ~~granite~~ <sup>Beth side</sup> granodiorite <sup>enclosed</sup> ~~occurs~~ <sup>in</sup> intruded the Skeena quartz diorite <sup>occurs</sup> near the north edge of the property.

Fault,  
Joint, and Vein Distribution

The property ~~was~~ was mapped at 1" = 1320' as part of the Guichon <sup>Creek</sup> Batholith <sup>project.</sup> ~~mapping~~ The <sup>geologic map,</sup> geology, supplemented by outcrops located from company maps, is presented in Figure 1.

On the basis of the 74 measurements which are represented in ~~Figures 2 and 3~~ <sup>and 3</sup> Figures 2 and 3 it is suggested that:

- (1. Most of the joints are steeply inclined,
- (2. Joints striking approximately 100° predominate,
- (3. ~~Other~~ ~~maxima~~ ~~and~~ ~~that~~ <sup>suggest</sup> joints ~~to~~ striking approximately 025, 065 and 160° <sup>are</sup> ~~are~~ <sup>common and</sup> equally well developed.

Faults occupied by veins

Veins ~~may~~ range widely in strike but those ~~from~~ <sup>with</sup> northerly and eastnortheast trends, are most common. Few faults and veins with copper mineralization were mapped but those seen correlate roughly with the northerly and easterly joint sets. Most of the dykes encountered strike northward or eastnortheastward. ~~Similarly,~~ Topographic lineaments <sup>have</sup> ~~found~~ similar trends.

## Veining

The most common types of veins <sup>consist of</sup> which occur are epidote with or without quartz, <sup>hematite,</sup> and chlorite. However, epidote-chlorite veins containing <sup>K</sup>potassic feldspar or sericite or calcite, and zeolite (laumontite) <sup>Barite was found in hole 71-4 in a vein.</sup> ~~massive~~ K-feldspar, <sup>and</sup> veins also occur are common. Copper and molybdenite mineralization occur with quartz, chlorite, epidote, and sericite-bearing veins. Rarely, <sup>explosion</sup> in breccias associated with (F.A. Carr, 1960) porphyry dykes tourmaline and hematite occur along with calcite, chlorite, and sericite.

## Alteration

In part, alteration is associated with veining and fracturing; the control in other instances is uncertain. <sup>argillic and</sup> Weak propylitic alteration are widespread. ~~and~~ Locally <sup>they</sup> are intensely developed. Relatively better phyllic and potassic alteration occur locally. ~~Best~~ grade mineralization is usually <sup>found</sup> ~~located~~ <sup>in</sup> ~~zones~~ <sup>relatively</sup> more intensely altered zones. eg drill holes 71-3, 71-8, 71-9, 71-11, 71-12 (Table 25). Twenty-six thin sections were examined ~~of~~ <sup>of</sup> core samples from the 1971 drilling. In virtually every sample mafic minerals <sup>are altered</sup> ~~are~~ altered to chlorite with or without calcite <sup>and/or epidote</sup> and feldspars to clay minerals, sericite, or sericite <sup>plus calcite</sup> ~~plus~~. Plagioclase color <sup>was variously</sup> ~~varied~~ from pink <sup>or</sup> light to dark green but alteration minerals did not vary. Perhaps the oxidation state of finely disseminated iron oxide <sup>within it</sup> controls plagioclase color.

However, ~~Iron~~ kaolinite has been identified by x-ray analysis as the major component in <sup>zones</sup> ~~areas~~ where plagioclase has altered to a soft, white, chalky-textured mineral aggregate.

overall - veining, ~~mineralization~~ <sup>in character</sup> and alteration are similar to that at Highmont

Alteration (continued)

The best mineralization encountered was in hole 71-11 from 450 to 500 feet. Two thin sections from this zone revealed quartz-poor rock in which plagioclase <sup>is partially</sup> ~~is~~ altered to chlorite, calcite, and sericite. In one specimen interstitial calcite is prominent; in the other, finer grained areas of intergrown quartz, calcite, and feldspar occur. Bornite <sup>is the</sup> predominant ~~is~~ copper sulphide in the zone and is associated with flaky sericite, calcite and hematite.

Alteration was apparently <sup>in part</sup> earlier than ~~and~~ <sup>and in part</sup> synchronous with veining and mineralization. ~~It~~ Judging by alteration in them it was at least in part <sup>emplacement of</sup> later than ~~the~~ aplites and porphyry dykes. Locally, the dykes and aplites are ~~veined and~~ <sup>veined and</sup> mineralized and some of the dykes are brecciated.

Occurrence of Showings and Mineralization

Chalcopyrite, bornite, molybdenite and minor amounts of pyrite occur in shear zones, <sup>breccias,</sup> alteration zones, and veins on the Sheba property. Where fracturing, alteration and vein development are most intense, grades are best.
