Weekly Report - Brans Group

New members - Jean Pantler, Julia O'Connor, Kim D'Arcy, Louis Farullo,  
James Lawton

Farullo, Lawton & Mark Mason cut baseline breeding  
property from 105 On to 105 20m soil sampling at 100m  
intervals. Thereafter lines were cut + sampled from 55 to  
15 & along lines 5n to 15n. Lines 5 and 6n were soil  
sampled at 100m intervals, the rest at 50m intervals.  
Lines 7 and 8n were incorrectly cut initially and were  
redone. The corrected lines are identified with sample  
numbers 81 XTABR. Sample numbers and location are  
given by grid co-ordinates. Samples were plotted at  
1:5000 on an air photo.

O'Connor + D'Arcy did detailed mapping of Bran Creek  
at a scale of 1:1000 from approximately 80 T 8 W 520 (Station A)  
to the point at which Bran Creek meets the # main  
tributary shown on Basal Lake Reconnaissance Geology  
map Sheet 93F/14E. Mapping was accomplished using  
compass and 50m chain for locations. Final station H7  
can be used as a control point because of its situation  
at intersection of creek + tributary. Information  
obtained was plotted at 1:1000 on graph paper and  
at 1:5000 on an air photo.

Pantler mapped the Bran Graps at a scale  
of 1:5000 and prospected the area.

During detailed mapping of Bran Creek and area the following rocks units were recognized:

① Andesite - this varied from fine to coarse grained to porphyritic with plagioclase phenocrysts. On a fresh surface the rock was grey-green weathering to a rusty dark brown. Kalinized plagioclase and manganese staining were common. The andesites were well jointed with minor pyrite, specularite, calcite and epidote. Small calcite veins were found in the andesite but they rarely exceeded 2cm in width and were generally unmineralized. Two larger larger veins were found, roughly 6cm wide, in fractures in the andesite and were rust stained on either edge of the vein with gauge material towards the centre. Chip samples were taken of these veins.

The andesite was always magnetic. This was the predominant rock type in the creek. On our map we have not distinguished between the various phases of the andesite.

② Lapille Tuff - this rock was purplish on a fresh surface weathering to a light grey colour with felsile parting. The rock contains angular rock fragments ranging in size from less than 1mm to 1.5 cm. Fragments were of andesitic composition and the tuff generally seemed to be associated with andesitic flows. This rock type was very common downstream in the area of the tributary.

③ a) Dacite - this was a cryptocrystalline light green rock with conchoidal fracture. It occurred as flows and dykes, but in minor amounts. This rock type was not mineralized.

b) Dacitic Tuff - this was a fine grained rock, buff coloured on a weathered surface with traces of a rusted out mineral, possibly pyrite. This was also a minor phase.

④ Basalt - this was generally porphyritic with plagioclase phenocrysts but also occasionally amygdaloidal. The rock is dark

grey-brown on a weathered surface and purplish on a fresh surface. This was also a minor phase.

⑤ Granodiorite - this was a medium to coarse grained euhedral-pinkish rock, weathering to a dark brown. This rock type was magnetic, contained minor pyrite and was well jointed. A gradational contact was observed with the andesite at one point.

⑥ a) Conglomerate - this rock had a greenish matrix of fine clay size particles with rounded to subrounded pebbles of 2mm to 25mm. The rock is poorly sorted and weathers a light grey.

b) Conglomerate - this was a dark brown-grey rock, very weathered, with rounded to subangular rock fragments from 1mm to 30cm. The rock fragments are of various volcanic compositions, mainly andesitic. Rock is very poorly sorted.

Geology of the creek is basically a series of andesitic flows intermixed with minor amounts of basalt, obsidian, dacitic tuff and lapilli tuffs. Lapilli tuffs are the predominant rock type at the end of the creek from station EE to HH, otherwise the andesite was dominant. I believe these rocks are part of the andesite unit of the Ootaa Lake Formation.

Contacts between units generally N-NE & calcitic veining associated with mineralization seems to follow principal joints.
